ACKNOWLEDGEMENTS

I would like to begin by thanking GOD for granting me the ability to complete this work.

I wish to extend my deepest appreciation and thanks to Prof. Dr. Gamal Gamal Eldin Youssef, Professor of Obstetrics and Gynecology Faculty of Medicine – Cairo University, for granting me the privilege of working under his supervision for his diligence, encouragement, helpful suggestions and invaluable help he rendered during the course of this work.

I am very grateful to Ass.Prof.Dr. Hala AbdElwhab AbdEltef, Lecturer of Obstetrics and Gynecology Faculty of Medicine – Cairo University, for her kindness, continuous help and encouragement to complete this work

I feel truly indebted to Dr. Hassann Mustafa Gaafar, Lecturer of Obstetrics and Gynecology Faculty of Medicine – Cairo University, for his point research suggestion, his active skillful participation and great cooperation through his work, without which this work would have never been accomplished.

Abstract

Intrauterine growth restriction (IUGR) has well-recognized perinatal and long term consequences. Because not all fetuses that are found to be small in utero have true growth restriction, the distinction of placental insufficiency from constitutional smallness has been one of the goals of fetal medicine over the last 20 years. Although intrauterine growth-restricted (IUGR) fetuses develop protective mechanisms, such as increased blood flow and oxygen uptake, they have an increased risk of developing signs of brain damage at birth.

Our study was a prospective observational study that aimed to analyze the possible existence of differences in the volume of fetal intracranial structures between IUGR (symmetric and asymmetric) and appropriate-for-gestational age fetuses in relation to MCA Doppler to determine cases with brain sparing effect and whether there is corresponding change in brain volume in relation to MCA Doppler changes.

In our study, 160 patients were included from those attending the Obstetrics and Gynecology department, fetal medicine unit at Kasr AL Aini hospital, Cairo University. We used VOCAL, which provides a semiautomatic delineation that frequently requires manual adjustments by the operator. VOCAL was selected instead of a multiplanar technique because this method requires less time to calculate volumes and has acceptable reproducibility. A technically successful measurement was obtained in all cases. Fetal brain volume data demonstrate a statistically significant linear increase of fetal brain volume relative to gestational age. Weekly increase in fetal brain volume is 20.51cm^3 for IUGR and 22.53 cm^3 for AGA. The fetal BV in IUGR is 296.366 cm^3 . In AGA group the fetal BV is 335.284 cm^3 .

Key words: IUGR; Doppler; Three-dimensional ultrasound; VOCAL

Introduction

Intrauterine growth restriction (IUGR) has well-recognized perinatal and long term consequences. Because not all fetuses that are found to be small in utero have true growth restriction, the distinction of placental insufficiency from constitutional smallness has been one of the goals of fetal medicine over the last 20 years (**Cruz-Martinez et al., 2009**). The most widely used sign to identify placental insufficiency and consequently to diagnose IUGR is an elevated pulsatility index (PI) in the umbilical artery (UA) (**Lackman et al., 2001a; Lackman et al., 2001b**). Small fetuses with normal UA Doppler findings are defined normally as small-for-gestational-age (SGA), and earlier reports suggested that they essentially might represent constitutionally small fetuses (**Soothill et al., 1999**).

However, recent evidence suggests that this diagnostic category contains a proportion of cases with true forms of fetal growth restriction, where the degree of placental insufficiency is not reflected in the UA Doppler findings. Thus, studies over the last decade have provided evidence that, on average, SGA fetuses have significantly poorer perinatal outcomes (**McCowan et al., 2000; Doctor et al., 2001; Severi et al., 2002**). In addition, a considerable proportion of these fetuses show abnormal neurobehavior neonatally (**Als et al., 1976; McCowan et al., 2002; Padidela and Bhat, 2003**) and abnormal neurodevelopmental tests in childhood, (**Figueras et al., 2008**) with features similar to those described for children who have IUGR (**Tolsa et al., 2004; Feldman and Eidelman, 2006**). Because the identification of SGA fetuses with true growth restriction cannot be based on UA Doppler findings, assessment of fetal signs such as brain circulation changes could be used for these purposes (**Hershkovitz et al., 2000; Severi et al., 2002; Habek et al., 2007**). Chronic fetal hypoxia is associated consistently with increased brain perfusion, which is also defined as brain sparing (**Scherjon et al., 1993**). In clinical practice, brain sparing is identified by a middle cerebral artery (MCA) Doppler PI below the 5th percentile (**Dubiel et al., 2002**). Recent studies have demonstrated that a proportion of SGA fetuses with MCA vasodilation have poorer perinatal outcome

Introduction

(**Hershkovitz et al., 2000; Severi et al., 2002**) and a higher risk of abnormal neurobehavior neonatally (**Oros et al., 2007**) at 2 years of age (**Eixarch et al., 2008**). These studies support the use of brain Doppler evaluation to distinguish SGA with growth restriction from constitutional smallness.

Although intrauterine growth-restricted (IUGR) fetuses develop protective mechanisms, such as increased blood flow and oxygen uptake, they have an increased risk of developing signs of brain damage at birth (**Fouron et al., 2001; Padilla-Gomes et al., 2007; Gonzalez et al., 2007; Benavides-Serralde et al., 2009**). The brain is particularly sensitive to changes in oxygen and glucose concentration. Studies performed in neonates and in young adults born with intrauterine growth restriction have shown that signs of neurological damage can be manifested later in life as low scores in neuro developmental tests and reduced cognitive function (**Majnemer et al., 1993; Upadhyay et al., 2000; Tideman et al., 2007**). Neonatal studies using brain biometry and volume segmentation have demonstrated the existence of selective growth restriction in certain brain regions (**Makhoul et al., 2004; Duncan et al., 2005**), which could explain subsequent alterations in neurodevelopment. Whether these changes occur in utero is unknown.

Aim of the work

In the present study, we aimed to analyze the possible existence of differences in the volume of fetal intracranial structures between IUGR (symmetric and asymmetric) and appropriate-for-gestational age fetuses in relation to MCA Doppler to determine cases with brain sparing effect and whether there is corresponding change in brain volume in relation to MCA Doppler changes
