

Exercise, Smoking, and Calcium Intake as Determinants of Peak Bone Mass

Thesis

Submitted for Partial Fulfillment of MD Degree in
Internal Medicine

By

Sally Nabil Abo Elsoued

Assistant Lecturer of Internal Medicine, Fayoum University

Under Supervision of

Prof. Dr. Soliman Nasr

Professor of Internal Medicine & Endocrinology
Faculty of Medicine, Cairo University

Prof. Dr. Amin Roshdy

Professor of Internal Medicine & Nephrology
Faculty of Medicine, Cairo University

Prof. Dr. Souad Soultan

Professor of Internal Medicine
Faculty of Medicine, Cairo University

Cairo University
2013**

ABSTRACT

Evidences emerging to suggest that osteoporosis is a global epidemic increasing worldwide. Lifestyle risk factors as the amount of calcium intake, exercise, smoking & caffeine consumption are important in determining BMD. We studied 1001 subjects, 726 were females & 275 were males between 20-70 years, for all subjects weight, height, Self assessment questionnaire & peripheral radial DXA were done. BMD is strongly related to age, sex, menopausal status, amount of calcium intake, the smoking state performance of exercise high caffeine consumption.

Key word: BMD, T-score, DXA, BMI

ACKNOWLEDGMENT

First and foremost, all the thanks to ALLAH the most beneficial and merciful.

I would like to express my deepest gratitude to Prof. Dr. Soliman Nasr, Professor of Internal Medicine & Endocrinology, Cairo University, I had the honor to proceed with this work under his instructive supervision, and guidance to enrich my study with her experience and knowledge throughout the steps of this work.

I would like to express my profound thanks to Prof. Dr. Amin Roshdy, Professor of Internal Medicine & Nephrology, Cairo University, for his supervision of this work, step by step in all its stages, for her constant encouragement and support.

I am very grateful to Prof. Dr. Souad Soultan, Professor of Internal Medicine, for her help and her valuable supervision throughout the practical part of this work.

Last and not least, I would like to thank my family; who supported me throughout this entire process. I owe to them every success I have ever achieved.

ARABIC SUMMARY	

INTRODUCTION

Peak bone mass in young adults is a major determinant of bone mass later in life. Thus even though most osteoporotic fractures occur in elderly people, the risk of osteoporosis may be profoundly affected by events in early life. Genetic factors play a major part in the determination of peak bone mass, accounting for up to 80% of the variance (**Ralston et al 2001**), but 20% or more may be due to environmental factors, including exercise, smoking and calcium intake.

To date, the role of calcium intake in achieving peak bone mass has been most convincingly supported by prospective interventional studies (**Dawson-Hughes et al., 2005**) and that of exercise in a cross sectional study of children aged 5-14 (**Wolff I et al., 1999**). The effect of smoking has not been studied in Egyptian adults groups.

Over the past 15 years, much has been learned about the epidemiology of osteoporosis in white women, particularly those aged 65 years and older. The study of osteoporotic fractures (SOF) in the United States and the EPIDOS study in France have been particularly useful in defining risk factors for fractures and characterizing the relationship between bone mineral density (BMD) and fracture risk.

In recent years, there has been increasing interest in osteoporosis among Egyptian women. Calcium intake is generally very low among Egyptians. Larger and longer-term studies are needed to test whether calcium supplementation can help increase bone mass (and possibly later bone strength) in geographic regions with low dietary calcium intake.

AIM OF WORK

To evaluate the contribution of exercise, smoking and calcium intake on BMD in Egyptian adults. Peripheral DXA scan will be used as an easy, cheap and accurate way of measurement of BMD.

CHAPTER I

Pathogenesis of Osteoporosis

Osteoporosis is a skeletal disorder characterized by low bone mass with microarchitectural disruption and fragility, resulting in an increased risk of fracture (table 1) (CDC, 1993; Raisz, et al 2005).

Category	Bone mass
Normal	A value for bone mineral density (BMD) within one standard deviation of the young adult female reference mean (T-score greater than or equal to -1 SD).
Low bone mass (osteopenia)	A value for BMD more than one but less than 2.5 standard deviations below the young adult female reference mean (T-score less than -1 and greater than -2.5 SD).
Osteoporosis	A value for BMD 2.5 or more standard deviations below the young adult female reference mean (T-score less than or equal to -2.5).
Severe (established) osteoporosis	A value for BMD more than 2.5 standard deviations below the young adult female reference mean in the presence of one or more fragility fractures.

Diagnostic categories for osteopenia and osteoporosis based upon bone mass measurements (Scientific Group. 2007; WHO, Geneva).

Elements that distinguish it from other causes of low bone mass, such as hyperparathyroidism and osteomalacia, include normal serum calcium and phosphorus and microarchitectural disruption without an increase in unmineralized osteoid. (figure 1).

Age-related loss of trabecular bone

Fig. (1): The figure shows normal bone in panel A, and progressively more osteoporotic bone in panels B, C and D

The bone that is present is normally mineralized, which distinguishes osteoporosis from osteomalacia. There is disruption of the normal architecture, as illustrated in the figure, panel D (figure 1). There are fewer bony spicules in osteoporotic bone and they are thinner than normal; in addition, there are disrupted horizontal "struts" that do not join up to any other structure, and thereby provide no structural support.

This microarchitectural disruption undermines the structural integrity of the bone, and leads to the major clinical features of osteoporosis: skeletal fragility and an increase in fracture risk [1](**CDC, 1993**) .

The mechanisms of the microarchitectural disruption are not clear. Increased remodeling itself may cause structural weakening, which may account for the independent association of high bone turnover with fracture risk (**Garnero, et al 1996**). Other possible factors include: Microfractures and fatigue damage The development of perforations and discontinuities in trabecular bone, as well as a relatively excessive loss of horizontal trabeculae (show figure 1) "Macroarchitecture" may play a role; as an example, increased length of the femoral neck appears to increase the risk of hip fracture Posture, muscle strength and the frequency and type of falls affect fracture frequency and site.

Decreased bone mass can occur because peak bone mass is low, bone resorption is excessive, or bone formation during remodeling is decreased. All three processes are likely to contribute, in varying degrees, to osteoporosis in individual patients. Their relative contribution to fracture risk is not known, but it seems likely that increased bone resorption has the greatest impact (**Melton, et al 1997; Garnero, et al 1996**).

Age- and menopause-related bone loss are clearly important pathogenetic factors, but their expression must vary because there are wide variations in the amount of bone and the amount of "porosity" of bone in older persons of the same age (figure 1) (**Feik, et al 1997**).

Fig. (2): Variations in bone mass in the femur.

Mid-shaft of the femur from three women and three men over the age of 80. Despite the fact that all subjects were the same age and all of the women were postmenopausal and estrogen deficient, there is marked variability in cortical thickness and porosity. The reasons for these differences are not known.
