Abstract

The candidacy for implantation is considered separately for adults and children. As outlined in the 1995 National Institutes of Health (NIH) consensus statement on cochlear implantation, adult candidacy is noted as being successful in postlingually deaf adults with severe-to-profound hearing loss with no speech perception benefit from hearing aids. Prelingually deafened adults must be counseled in regard to realistic expectations, as language and open-set speech discrimination outcomes are less predictable. Children are considered candidates for implantation at age 12 months, and, because of meningitis-related deafness with progressive cochlear ossification, occasional earlier implantation is necessary.

To my
Mother,
Mahmoud sharaf,,,,,,,,

Acknowledgement

I wish to express my deep gratitude and thanks to Prof. Dr. Mohamed Abd Al-Rahaman Al-Shazly professor of Otorhinolaryngology – Cairo University for providing me with the initial stimulus which aroused my interest in this work.

Also, I want to express my deep thanks to Prof. Dr. Ahmed Hasan Khashaba professor of Otorhinolaryngology – EGYPTIAN Military Medical Academy for his valuable help & guidance, I want to tell him that you are my godfather, I had inspired everything from you.

At first and end all thanks should be for my God.

INTRODUCTION

CHAPTER (1)

INTRODUCTION

Cochlear implant is a device that delivers electrical stimulation through an array of electrodes to a bundle of cochlear nerve fibers. And, it is established as an effective and safe method of rehabilitation for profoundly deaf patients (**Kim et al., 2004**).

In 1957, Djourno and Eyries made the observation that activation of the auditory nerve with an electrified device provides auditory stimulation in a patient. This observation was considered the seminal observation that paved the way for modern cochlear implantation. In 1963, Doyle J, and Doyle D's early experiments in scala tympani implantation preceded the first House/3M single-channel implant in 1972. Multichannel devices introduced in 1984 have replaced single-channel devices by virtue of improved speech recognition capabilities. As of 2006, nearly 100,000 cochlear implants are estimated to have been performed worldwide (**Megerian and Murray, 2006**).

Cochlear implants are the first true bionic sense organs. The human cochlea is an electromechanical transducer. Cochlear implants, like other human hair cell, receive mechanical sound energy and convert it into a series of electrical impulses (**Roland et al., 2003**).

Sound is first detected by a microphone (usually worn on the ear) and converted into an analog electrical signal. This signal is then sent to an external processor where it is transformed into an electronic code. This code is transmitted via radiofrequency across the skin by a transmitting coil. Ultimately, this code is translated by the receiver-stimulator into rapid electric impulses distributed to electrodes on a coil implanted within the cochlea (**Driscoll et al., 2004**).

Introduction

The candidacy for implantation is considered separately for adults and children. As outlined in the 1995 National Institutes of Health (NIH) consensus statement on cochlear implantation, adult candidacy is noted as being successful in postlingually deaf adults with severe-to-profound hearing loss with no speech perception benefit from hearing aids. Prelingually deafened adults must be counseled in regard to realistic expectations, as language and open-set speech discrimination outcomes are less predictable. Children are considered candidates for implantation at age 12 months, and, because of meningitis-related deafness with progressive cochlear ossification, occasional earlier implantation is necessary. Investigations are ongoing into extending the age of early routine implantation to younger than 12 months. audiological criteria include severe-to-profound sensorineural hearing loss bilaterally and poor speech perception under best-aided conditions, with a failure to progress with hearing aids and an educational environment that stresses oral communication (**Megerian and Murray, 2006**).

During the last twenty years, the indications for cochlear implants (CIs) extended significantly due to positive experience with CIs, improved CI technology, and safer surgery. Providing a postlingually deaf adult with a unilateral CI and prelingual child younger than 5 year have been the earliest indication and remains the standard indication. However, CIs are also indicated for prelingually deaf adults, and for children younger than one year old. Recently, CIs are also indicated for adults with residual hearing; when best aided sentence recognition scores in quiet are lower than 70%. CIs for patients with residual hearing sometimes imply the use of bimodal CI; a device that stimulates the cochlea both electrically and acoustically. Another promising evolution is bilateral implantation. Nowadays it has also become possible to place a CI in the malformed cochlea (**Deggouj et al., 2007**). .
