#### Introduction

Reproductive health interventions that target couples are found to be more effective than those directed to only one sex. The evidence justifies a focus on couples who need to be aware of what forms of contraception to use. Men could also be given messages about their own reproductive health, encouraged to take part in child care and to appreciate daughters equally with sons (Becker, 1996 and Blaney 1997).

According to a review of male involvement programmes in more than twenty developing countries, this review advocates 1) changing the social norms that govern male behaviour in sexual relations and parenthood. 2) incorporating male involvement in overall planning of reproductive health programmes. 3) and adapting service delivery programmes to make them more male friendly. The aims were 1) to increase men's awareness of the need to safeguard reproductive health 2) to increase men's support of their partner's reproductive health choices, and 3) to increase the use of male methods of contraception for those who wish to do so. (Schehl, and Green, 1997).

The most frequently mentioned reason given for not intending to use contraception is that the woman is menopausal or has undergone a hysterectomy (23 percent). Another reason given by sizeable proportions of women is that the woman wants as many children as possible (17 percent). Among the group who discontinued

contraception, the most commonly mentioned reasons are that they wanted to have a child (29 percent) or that the method created a health problem or a menstrual problem (21 percent). (Baumann and Deber, 1995).

Among the currently married non-pregnant women who never used contraception, the most commonly mentioned reason for not currently using a method is the need for more children (45 percent). There are no substantial urban-rural differences in reasons for not currently using contraception (Orobaton, 1995).
