

**SERUM LEVEL OF  $\beta$ -HUMAN CHORIONIC  
GONADOTROPIN AS A PREDICTOR FOR  
ABNORMAL KARYOTYPE OF FIRST  
TRIMESTER ANEMBRYONIC PREGNANCY**

Thesis

*Submitted for Partial Fulfillment of  
Master Degree in Obstetrics and Gynecology*

By

**AMIR FAWZY YOUSSEF AHMED**

M.B., B.Ch., Al Azhar  
Mattaria Teaching Hospital

Under Supervision of

**Dr. Magdy Mohamed Mahmoud Abd El  
Gawwad**

*Professor of Obstetrics and Gynecology  
Faculty of Medicine  
Ain Shams University*

**Dr. Ezzat Sayed El-Sobky**

*Professor of Genetics  
Faculty of Medicine  
Ain Shams University*

**Dr. Ibrahim Anwar Ahmed**

*Assistant Professor of Obstetrics and Gynecology  
Faculty of Medicine  
Ain Shams University*

Faculty of Medicine  
Ain Shams University

## Acknowledgement

First and foremost thanks to **ALLAH** whose magnificent help was the reason of accomplishing this work

*I would like to express my sincere thanks and deepest gratitude to Professor Dr. Magdy Mohamed Mahmoud Abd El Gawwad, Professor of Obstetrics and Gynecology, Faculty of Medicine, Ain Shams University, for his gracious supervision, valuable guidance, generous help, support and continuous encouragement through the whole research. I am deeply affected by his noble character, perfection, care and consideration. I am very much privileged and honored to have him as my supervisor. To him I owe much more than I can express.*

*I would like to express my deepest appreciation and gratitude to Dr. Ezzat Sayed El-Sobky, Professor of Genetics, Faculty of Medicine, Ain Shams University, for giving me the privilege of working under his supervision, patience, constructive criticism, valuable guidance, unlimited time and effort.*

*I would like to express my deep appreciation and gratitude to Dr. Ibrahim Anwar Ahmed, Assistant Professor of Obstetrics and Gynecology, Faculty of Medicine, Ain Shams University, for giving me the privilege of working under his supervision and for his helpful guidance.*

*Last but not least I would like to express my deepest thanks and gratitude to my colleagues and to every one in my family.*

## Dedication

*To my Parents. For their encouragement and support.*

*To my ever supporting, loving Wife, for her tremendous  
encouragement, support, understanding and love.*

*To my lovely son Mahmoud*

## INTRODUCTION

Anembryonic pregnancy (blighted ovum) is a frequent form of loss, that is present between 16% and 30% of all pregnancies (*West, 1993; Coulam et al., 1994*) and in up to 40% of ectopic pregnancies (*Emmrich and Kopping, 1991*).

Early recurrent pregnancy losses still constitute a major dilemma for many obstetricians and infertility specialists. It remains a major area of research in many centers involved in reproduction and immunology (*Rubio et al., 2000*).

Chromosomal anomalies are present in 10% of all first trimester abortions (*Coulam et al., 1994; Hassold and Hunt, 2001*). Anembryonic pregnancy has been associated with chromosomal anomalies in up to 14% of cases (*Minelli et al., 1993*); this findings suggests a high probability of gestational loss.

Approximately 50% of such miscarriages are associated with cytogenetic abnormalities, with trisomy being the most frequent, followed by polyploidy and monosomy X (*Stephenson et al., 2002*).

The earlier the pregnancy loss occurs, the greater the likelihood of genetic causation. Among first trimester

abortions, 30% to 40% show chromosomal abnormalities, usually aneuploidy (*Simpson, 1996*).

Although routine cytogenetic analysis of miscarriages has remained an uncommon practice to date, the results help the physician to decide whether further investigations are warranted. In addition, the results are useful in the counseling of couples who are trying to understand why their pregnancy ended in miscarriage and to decide whether to try again (*Stephenson et al., 1997*).

The hormonal changes and maternal adaptations of human pregnancy are considering the most remarkable phenomena in nature. Endocrinologic parameters in early gestation period have been used to predict abnormal pregnancies and identify fetuses that have chromosomal aberrations (*Engin et al., 1994*).

In the last decade there has been a gradual shift away from the mid trimester screening toward first trimester screening the purported advantages of first trimester screening include early reassurance with normal results, early diagnosis of fetal disorders. So the question was whether these markers were also of value in first trimester screening? (*Ray et al., 1994*).

## **AIM OF THE WORK**

The purpose is to establish the possible correlation between karyotype of first trimester anembryonic pregnancy and serum level of  $\beta$ -hCG.

## **HUMAN CHORIONIC GONADOTROPIN (hCG)**

### **Chemical Characteristics:**

#### *Human chorionic gonadotropin (hCG)*

Human chorionic gonadotropin is a glycoprotein, a peptide framework to which carbohydrate side chains are attached. The long half life of hCG is approximately 36 hours as compared with two hours for luteinizing hormone (LH), a 18-fold difference, which is due to mainly to the greater sialic acid content of hCG. As with the other glycoproteins, follicle stimulating hormone (FSH), LH, and thyroid stimulating hormone (TSH) (*Cunningham et al., 2007*).

hCG consists of two subunits, called alpha ( $\alpha$ ) and beta ( $\beta$ ). The  $\alpha$  subunit in these glycoprotein hormones is identical, consisting of 92 amino acids. Unique biologic activity as well as specificity in immunoassays is attributed to the molecular and carbohydrate differences in the B subunits (*Speroff et al., 2009*).

B-hCG is the largest B subunit, containing a larger carbohydrate moiety and 145 amino acid residues, including a unique carboxyl terminal tail piece of 34 amino acid residues, including a unique carboxyl terminal tail piece of 34 amino acid groups. It is this unique part of the

hCG structure that allows the production of highly specific antibodies and the utilization of highly specific immunologic assays (*Laphorn et al.*, 1997).

The extended sequence in the carboxyl terminal region of B-hCG contains four sites for glycosylation, the reason why hCG is glycosylated to a greater extent than LH, a difference that is responsible for the longer circulating half life for hCG (*Speroff*, 2000).

All human tissues appear to make hCG, but the placenta is different in having the ability to glycosylate the protein, thus reducing its rate of metabolism and giving it biologic activity through a long half life (*Gharib et al.*, 1990).

## **Biosynthesis**

The synthesis of the  $\alpha$  and the  $\beta$  chains of hCG is regulated separately. A single gene located on chromosome 6 encodes the  $\alpha$ -subunit of all four glycoprotein hormones – hCG, LH, FSH and TSH. There are seven separate genes on chromosome 19 for the  $\beta$ -hCG- $\beta$ -LH family. Six of these genes code for  $\beta$ -hCG genes are expressed at significant levels. Both the  $\alpha$  and  $\beta$ -subunits of hCG are synthesized as larger molecular weight precursors, which are cleaved by microsomal endopeptidases. Once intact hCG is assembled, the molecule is rapidly released from the

cell through exocytosis of secretory granules (*Miller-Lindholm et al.*, 1994; *Cunningham et al.*, 2006).

The hCG B subunit promoter does not contain steroid hormone response elements, allowing hCG secretion to escape feedback regulation by the sex steroid, in contrast to FSH and LH. Using recombinant DNA technology, it has been demonstrated that there is a single human gene for the expression of the  $\alpha$ -subunit. The gene for the  $\alpha$ -subunit shared by FSH, LH, hCG, and TSH is located in chromosome 1p21.23. A single promoter site subjects to multiple signals and hormones regulates transcription of the  $\alpha$  gene in both placenta and pituitary (*Albanese et al.*, 1996).

The gestational profiles of total amounts (free plus combined) of alpha and beta hCG subunits increased together and peaked at 9-10 weeks of gestation. Thereafter total alpha and beta subunits decreased and subsequently remained stable until term. The decline in total alpha hCG subunit is less marked than that of total beta hCG subunit. The alpha to beta hCG ratio was equimolar until 10 weeks of gestation when it increased almost four fold until term (*Nagy et al.*, 1994).

The genes that encode for the  $\beta$ -subunits of LH, hCG, and TSH are located in a cluster on chromosome 19q13.2. There are six genes for the B subunit of hCG, and only one for B. LH. Transcription for the six hCG genes, each with different promoter activity, varies and it is not certain why

hCG requires multigenic expression (perhaps this is necessary to reach the extremely high level of production in early pregnancy). It is thought that  $\beta$ -hCG evolved relatively recently from B-LH, and the unique amino acid terminal extension of B-hCG arose by a read through mutation of the translation stop codon in the B-LH gene; the DNA sequences of the B-hCG genes and the B-LH gene are 96% identical (*Maston et al.*, 1997).

The genetic complexity for the transcription of B-hCG raises the possibility for mutations of these genes as causes of reproductive problems. A search for B-hCG gene deletions in women with recurrent miscarriage or unexplained infertility and for duplications in women with gestational trophoblastic neoplasia found only normal gene structures (*Layman et al.*, 1994).

## **Cellular Origin**

*Cellular origin of hCG.* The origin of hCG appears to vary depending on the time in gestation. At less than 6 weeks, hCG expression is observed in both syncytiotrophoblast and cytotrophoblast cells. Later in gestation, when maternal serum levels are at their peak, hCG is produced almost solely in the syncytiotrophoblast. The amounts of hCG mRNA for both  $\alpha$ - and  $\beta$ -subunits in syncytiotrophoblast from the first trimester are greater than at term, which may be an important consideration when used as a screening procedure to identify abnormal fetuses

(*Kurman et al.*, 1984; *Beck et al.*, 1987; *Maruo et al.*, 1992).

hCG gene expression is present in both cytotrophoblasts, but it is synthesized mainly in the syncytiotrophoblast. The maternal circulating hCG concentration is approximately 100 IU/L at the time of the expected but missed menses. A maximal level of about 100,000 IU/L in the maternal circulation is reached at 8-10 weeks of gestation (*Nakajima et al.*, 1990).

All human tissues appear to make hCG, but the placenta is different in having the ability to glycosylate the protein, thus reducing its rate of metabolism and giving it biologic activity through a long half life. The carbohydrate components of the glycoproteins are composed of fructose, galactose, mannose, galactosamine, glucosamine, and sialic acid. Although the other sugars are necessary for hormonal function, sialic acid is the critical determinant of biologic half life. Removal of sialic acid residues in hCG, FSH and LH leads to very rapid elimination from the circulation (*Speroff et al.*, 2000).

## **Regulation of hCG Synthesis**

hCG production and secretion are the result of complex interactions among the sex steroids, cytokines GnRH, and growth factors. GnRH is synthesized by placental cells; GnRH receptors are present on placental
