## **ACKNOWLEDGEMENT**

Thanks to **Allah** for blessing this work and guiding my efforts until it has reached its end as a little part of his generous help throughout our life. I would like to express my deepest gratitude and immense appreciations to **Prof. Dr. Ahmed**

**Mohammed Lotfy**, Professor of General Surgery, Faculty of Medicine, Ain shams university, for his valuable suggestions, endless support, precious guidance and for giving me much of his experience and encouragement throughout this work.

I would like to express my grateful thanks and respect to **Dr. Ahmed Elsayed Morad**, Assistant Professor of General Surgery, Faculty of Medicine, Ain shams university, for his close supervision, precious instructions and sincere support during performing this work.

My respectful thanks are for **Dr. Essam Fakhry Ebied**, Lecturer of General Surgery, Faculty of Medicine, Ain shams university, for giving me much of his experience and time during performing this study and for his great help and support.

## **Introduction**

Pancreatitis is an inflammatory disorder of the pancreas which occurs with an estimated incidence of 10-15 per 100,000 per year in the UK. Mild acute pancreatitis accounts for 80% of cases, is self-limiting, and usually resolves with simple supportive management in 3-5 days. Severe acute pancreatitis accounts for the remainder of cases and was defined by the Atlanta Symposium as acute pancreatitis associated with organ dysfunction or local or regional complications. Most deaths from severe acute pancreatitis result from sepsis and multiorgan failure. Mortality in patients with infected pancreatic necrosis is 20-30%, compared with 10-12% in those with sterile necrosis (*Simon et al., 2004*).

Severe acute pancreatitis is a very challenging disease with multiple complications and high mortality, early assessment of prognosis and severity is important (*Mayumi et al., 2007*).

Acute Pancreatitis is potentially lethal disease especially in its severe form, which accounts for approximately 20% of cases in patients hospitalized with Acute Pancreatitis. Mortality in severe diseases varies from 10% to 20% (*Kumar et al., 2007*).

The two major etiological factors responsible for acute pancreatitis are alcohol and cholelithiasis, the incidence of alcoholic pancreatitis is much higher in men than in women . The risk factors include endoscopic retrograde cholangiopancreatography, surgery, therapeutic drugs, human immunodeficiency virus infection, hyperlipidemia, and biliary tract anomalies .The recurrence rate of acute pancreatitis is relatively high, the incidence of chronic pancreatitis after acute attack ranges from 3% to 13% (*Sekimoto et al., 2006*).

Acute pancreatitis remains the most common complication of endoscopic retrograde cholangiopancreatography(ERCP). The incidence of post-ERCP pancreatitis varies from 1% to 4%.(*Li-Ming et al., 2009*).

The greatest change in the treatment of acute pancreatitis is that surgery has been transformed from an immediate measure in necrotizing disease to a late intervention. Although large prospective, multicenter studies are still lacking, the pendulum has swung towards conservative treatment across the world, conservative measures are tried first even in the presence of infected necroses. Surgical intervention is reserved for complications in the later stages of the disease (*Paul, 2010*).

Pancreatic debridement or drainage in patients with infected pancreatic necrosis and/or abscess confirmed by radiologic evidence of gas or results of fine needle aspirate, the gold standard for achieving this goal is open operative debridement. Minimally invasive technique including laparoscopic and/or percutaneous interventions might be effective in selected patients. Wherever possible, operative necrosectomy and/or drainage may be delayed at least 2 to 3 weeks to allow for demarcation of the necrotic pancreas (*Thunher et al., 2001*).

## **AIM OF THE WORK**

The aim of this study is to discuss causes, diagnosis and recent lines of management of severe acute pancreatitis.

## Chapter (1): Anatomy and Embryology of the Pancreas

---

## ANATOMY OF THE PANCREAS

The pancreas is divided into four parts-head, neck, body and tail - and it possesses one accessory lobe (the uncinate process). The division into the parts is purely on the basis of anatomical relations and there are only very minor functional or anatomical differences between them (*Jeremiah and Neil, १००A*).

In an adult, the pancreas weighs १० to १०० g and is about १० to १० cm long (*William et al., १०१*). With age, the amount of exocrine tissue tends to decline, as does the amount of fatty connective tissue within the substance of the gland, and this leads to a progressive thinning atrophy which is particularly noticeable on CT (*Neil et al., १००B*).

The pancreas lies within the curve of the first, second and third parts of the duodenum, and extends transversely and slightly upwards across the posterior abdominal wall to the hilum of the spleen, behind the stomach. It does not lie in one plane but is effectively 'draped' over the other structures in the retroperitoneum and the vertebral column and so forms a distinct shallow curve, of which the neck and medial body are the most anterior parts. Because of its flattened shape, the parts of the pancreas, particularly the body, are often referred to as having surfaces and borders (*Susan et al., १००A*).

## **Regions Of The Pancreas:**

### **a) Head of the pancreas :**

The head of the pancreas lies to the right of the midline, anterior and to the right side of the vertebral column. It is the thickest and broadest part of the pancreas. It lies within the curve of the duodenum. Superiorly it lies adjacent to the first part of the duodenum but close to the pylorus. The duodenal border of the head is flattened and slightly concave. Occasionally a small part of the head is actually embedded in the wall of the second part of the duodenum. The superior and inferior pancreaticoduodenal arteries lie between the head and the duodenum in this area. The inferior border lies superior to the third part of the duodenum and is continuous with the uncinate process. Close to the midline; the head is continuous with the neck. The boundary between head and neck is often marked anteriorly by a groove for the gastroduodenal artery and posteriorly by a similar but deeper deep groove containing the union of the superior mesenteric and splenic veins to form the portal vein (*Susan, १ • • १*).

The anterior surface of the head is covered with peritoneum and is related to the origin of the transverse mesocolon (*Jeremiah and Neil, १ • • १*).

The posterior surface of the head is related to the inferior vena cava, which ascends behind it and covers almost all of this aspect. It is also related to the right renal
