First of all, I should express my deep thanks to *Allah*, without his great blessing, I would never accomplish my work, and to whom I relate any success in achieving any work in my life.

I would like to express my sincere appreciation and deepest gratitude to Prof. Dr. Mohamed Hany Shehata, Professor of Obstetrics & Gynecology, Cairo University, for his meticulous advice, continuous encouragement and valuable instructions throughout this work. It was a pleasure and privilege to work under his guidance and supervision.

I would like to express my gratitude to Dr. Hisham Mohamed Gouda; Lecturer of Obs. & Gyn., Cairo University for his help & patience all through the time of the research.

Also, I would like my great regards to my aunt prof. Dr. Seham Mohamed Ali, prof. of botany. Faculty of science, Ain Shams University for her kind care and great help in this work.

Finally, I would like to thank all my family members for their support, help and love and their encouragement to me all through my life.

## INTRODUCTION

Prenatal diagnosis of inherited disorders is mainly based on genetic testing of fetal materials obtained from amniocentesis or chorionic villous sampling. These invasive procedures carry a significant risk for both fetus and mother (Evans& Andriole, 2008; Forabosco et al., 2009), which burdens not only the affected pregnant women but also their family members (Grant& Yagel, 2001; Odibo et al., 2008; Cohen& Yagel, 2009). The discovery of circulating cell-free fetal DNA in maternal plasma opens a great hope for risk-free noninvasive prenatal diagnosis (NIPD) (Hahn et al., 2007; Lo, 2009).

Lo et al. (1998) demonstrated the presence of circulating cell- free fetal (ccf) DNA in the maternal circulation, which offered an approach for non invasive prenatal diagnosis (NIPD) (Redman& Wainscoat, 1997; Zhong et al., 2001). In addition, high levels of ccf DNA in plasma and serum samples have been widely described in a variety of clinical pathological conditions such as pathological pregnancies, inflammatory diseases and trauma (Lederrey& Stroun, 2001; Lo, 2001). These findings suggest that ccf DNA may help in understanding the biological nature of disease and be of use in clinical diagnostic applications (Anker& Stroun, 2001; Stroun& Anker, 2000; Lo, 2008).

Circulating cell free DNA has been found in the plasma of human subjects (Wochenschr, 1999; Clin, 1980). Recent applications of molecular biologic techniques have allowed the molecular characterization of circulating DNA in certain pathologic and physiologic conditions. Thus, tumor associated genetic changes have been found in the plasma and serum of patients suffering from a

number of cancers (Nat Med 1996; Clin, 1998). After solid organ transplantation, donor-derived DNA has also been found in the plasma of the recipients (Lancet 1998). Physiologically, fetal derived DNA has been found in the plasma and serum of pregnant women (Lancet, 1997). Taken together, these studies indicate that circulating non host DNA is a common phenomenon in many clinical and physiological scenarios.

Lo et al. (1997) stated that the rapidly growing fetus and placenta possessed tumor like qualities. Due to much similarity between the placenta and malignant tumor, some investigators termed the placenta "pseudo-malignant"(Strickland& Richard, 1992). Such a similarity suggests that just as tumor DNA can be found in the circulation of cancer patients, fetal DNA may also be found in maternal plasma.

Because invasive techniques of prenatal diagnosis such as amniocentesis and chorionic villous sampling are expensive and associated with risks to mother and fetus, alternatively non invasive methods are being actively explored (Haematol, 1999).

The presence of extra-cellular fetal DNA in maternal plasma has recently been demonstrated (Lo et al., 1998). Little is known about the physiological or pathological factors affecting its release into and clearance from the maternal circulation. It has been observed that fetal DNA concentration in maternal plasma increases in pregnancy complications associated with placental abnormalities, such as hypertension and hypertensive disorders (Lo et al., 1998). This might probably be attributed to enhanced transplacental cell transfer and increased cell destruction, which might affect liberation, clearance or turnover of circulating DNA.

In contrast to the traditional teaching that the placenta forms an impermeable barrier between the pregnant women and her fetus, multiple studies show that both intact fetal cells and cell free nucleic acids circulate freely within maternal blood (Haematol, ۱۹۹۹).

The feto-maternal transplacental cell trafficking seems to be enhanced in pregnancies complicated by hypertensive disorders, where an increased flow of nucleated fetal cells (trophoblasts and erythroblasts) into maternal circulation has been demonstrated (Walknowska et al., ۱۹۶۹; Lo et al., ۱۹۸۹).

Hypertensive disorders is a serious pregnancy complication affecting ۵%-۷% of pregnancies and presented with high blood pressure and proteinuria (Levine et al., ۱۹۹۸). Frequently, this condition may also be associated with intrauterine growth retardation (IUGR). The HELLP (hemolysis, elevated liver enzymes, low platelets count) syndrome is considered to be a severe form of hypertensive disorders having an incidence between ۰,۳%- ۰,۸%, which is considerably lower than that of hypertensive disorders (Weinsten, ۱۹۸۲).

The pathogenesis of these disorders is not completely understood, but the primary common pathological pathways seem to be a failure of trophoblastic invasion of the spiral arteries, resulting in placental insufficiency (Robertson et al., ۱۹۸۶), which is associated with widespread apoptosis of cytotrophoblasts that invade the spiral arteries of the uterus (Difederico et al., ۱۹۹۹). In this regard, programmed cell death is one of the proposed mechanisms leading to fetal DNA release in maternal plasma. Presence of the fetal DNA in the maternal circulation results from the constant active remodeling of the placenta, with ongoing constant apoptosis and replacement of the placental cells at the maternal-fetal interface and

trans placental leakage of the fetal cells (trophoblast , lymphocyte , granulocyte , nucleated red blood cells and stem cells) Fetal DNA becomes detectable from the fifth month of the pregnancy (Clin, ୨୦୦୧).

These conditions remain a major cause of fetal and maternal morbidity and mortality (Mies et al., ୧୯୯୩). The danger of these pathologies is exacerbated by the fact that the maternal and fetal pathological signs can suddenly appear at any time from mid-second trimester until term. Despite improvement of criteria to identify the women at risk, no test is truly predictive of later development of these pathologies (Thom et al., ୧୯୯୦). Understanding whether abnormal patterns of fetal DNA may be detectable, even before the manifestation of clinical signs of these disorders, might result in a powerful test for the risk of developing these pathologies and allow one to adopt preventive strategies.

Lo et al., (୧୯୯୪) looked for fetal DNA in maternal plasma and serum, using the detection of Y- chromosome DNA sequences derived from a male fetus as a model system. This work produced the first demonstration of fetal DNA in maternal plasma and serum and realization that maternal plasma DNA is a chimeric mixture of fetal and maternal DNA. Before the demonstration of this chimerism, plasma and serum were discarded by investigators looking for nucleated cells in the maternal circulation (Clin, ୧୯୯୯; Houfflin et al., ୨୦୦୦).

Using commercial column- based DNA extraction methods and sensitive real-time PCR technique, sensitivity close to ୧୦୦% has been reached for the detection of a fetal- derived Y- chromosomal sequence from maternal plasma and serum (Lo et al., ୧୯୯୮). Using a sensitive tested- PCR protocol, Smid et al. (୧୯୯୯) was able to obtain very reliable detection of Y- chromosomal targets from maternal

plasma in women carrying male fetuses. In addition to improving the sensitivity of detection, the real time PCR system can be used to measure the concentration of fetal DNA in maternal plasma and serum (Lo et al., 2000).

Between the 11<sup>th</sup> and the 14<sup>th</sup> week of pregnancy the fetal DNA in the serum accounts for the 3,4% of the total maternal DNA, gradually rising to reach the level of approximately 6,2% between the 34<sup>th</sup> and 40<sup>th</sup> week of pregnancy. After birth, its concentration decreases rapidly, as a result of the increased renal filtration.

We aimed at this study to analyze the presence of fetal DNA expressed in copy numbers in the plasma of pregnant women with hypertensive disorders and to show that increased fetal DNA concentration represents a valuable marker for placental abnormalities. This rise in DNA may precede clinical manifestation of hypertensive disorders by few weeks.

**Aim of the work**

١. To analyze the presence of fetal DNA expressed in copy numbers in the plasma of pregnant women with hypertensive disorders complicated pregnancy.

٢. To prove that increase fetal DNA concentration represents a valuable marker of placental abnormalities. This rise in DNA may precede clinical manifestation of pre-eclampsia by few weeks.

٣. This study allows one to adopt preventive strategies to avoid complications.
