Recent Methods in Treatment of Congenital Nasolacrimal Duct Obstruction

Essay Submitted for the partial fulfillment of
Master Degree In Ophthalmology

By:

Karim Mohammed Tharwat Ibrahim Khairy
(M.B.B.ch.)

Faculty of Medicine- Zagazig University

Under Supervision of

Prof. Dr.Saad Mohammed Rashad

Professor of Ophthalmology

Faculty of Medicine - Ain Shams University

Dr.Mahmoud Ahmed El Samkarey

Lecturer of Ophthalmology

Faculty of Medicine - Ain Shams University

بسم الله الرحمن الرحيم

(قَالُوا سُبْحَانَكَ لَا عِلْمَ لَنَا إِلَّا مَا
عَلَّمْتَنَا إِنَّكَ أَنْتَ الْعَلِيمُ الْحَكِيمُ)

(سورة البقرة: آية 32)

Acknowledgements

First of all, thanks to **Allah** the most beneficent, the most merciful who helped me not only in this work, but all through my life.

I would like to express my deepest thanks to **Prof. Dr. Saad Mohamed Rashad**, Professor of Ophthalmology Department, Ain Shams University, for his kind care, valuable guidance, and precious instructions given, which guided me in this work.

Great gratitude and respect are to **Dr. Mahmoud Ahmed El Samkarey**, Lecturer of Ophthalmology, Ain Shams University, for his continuous encouragement, generous help, fruitful instructions and precious time he spent throughout this work.

Lastly, I would like to present my sincere thanks to all my professors and colleagues, for the fruitful atmosphere they provided me.

Karim Mohammed Tharwat

Embryology of lacrimal drainage system

The entire lacrimal drainage apparatus is of ectodermal origin, surrounded by muscles of mesodermal source.^[1]

In utero, a solid cord of epithelium forms in the region of the medial lower eyelid, eventually sending projections temporally to form the canaliculi and inferiorly to form the nasolacrimal duct. Thus, the puncta and the valve of Hasner are considered “embryologically distal” structures, explaining why most congenital abnormalities of tear drainage are found at these sites^[2]

Canalization of the solid cord begins at 4 months of gestation and may continue after birth. Indeed, the most inferior portion of the nasolacrimal duct is imperforate at birth in 50% to 70% of individuals.^[3]

At 5.5 weeks' gestation (Fig. 1-A), an ectodermal invagination forms between the lateral nasal process and maxillary process, which becomes pinched off from the surface. At 6 weeks' gestation (Fig. 1-B), a solid cord of ectoderm is located between the primitive medial canthus and nose.

At 12 weeks' gestation (Fig. 1-C), proliferation of the cord occurs laterally toward the eyelid and inferiorly toward the inferior turbinate. The isolated cavities shown appear at 3 to 4 months. At 7 months, canalization is nearly complete (Fig. 1-D), with only the puncta and valve of Henle remaining imperforate.^[4]

Fig. 1: Embryology of lacrimal drainage system ^[4]

Stages of the development of the human lacrimal drainage system:

(A) Formation of the lacrimal lamina (Carnegie stage 16-18 ca 39-44 days)

The ‘lacrimal lamina’ (LL) appears as an epithelial thickening of the lacrimal groove (LG) observed between the lateral nasal process (LNP) and the maxillary process (MxP). At Carnegie stage 18 the lacrimal lamina bifurcates at its medial extreme and is arranged lateral to the nasal cavity but without reaching it. ^[5]

(B) Formation of the lacrimal cord (Carnegie stage 19-23 ca 46-53 days)

The lacrimal lamina (LL) separates from the surface ectoderm to form the ‘lacrimal cord’ (LC). The lacrimal cord bifurcates at its lateral extreme and forms the superior & inferior lacrimal canaliculi (SLC and ILC). The mesenchyme surrounding the canalicular primordium condenses. ^[5]
