## Acknowledgments

*First and foremost, I feel always indebted to **Allah**, The **Most Beneficent** and **Merciful** Who gave me the strength to accomplish this work,*

*My deepest gratitude to my supervisor, **Prof. Dr. Ihab Zaki El-Hakim**, Professor of Pediatrics, Faculty of Medicine, Ain-Shams University, for his valuable guidance and expert supervision, in addition to his great deal of support and encouragement. I really have the honor to complete this work under his supervision. May Allah blesses him and keeps him a sun lightening the way for the scientific students.*

*I would like to express my great and deep appreciation and thanks to **Dr. Ragia Marei Ali Said**, Lecturer in Pediatrics, Faculty of Medicine, Ain-Shams University for her meticulous supervision, and her patience in reviewing and correcting this work; also for the efforts and time she has devoted to accomplish this work,*

*Special thanks to my **Parents**, to them I owe everything, my **Wife**, the backbone of my life and my **Children** my shiny stars without whose inspiration none of this would have been possible.*

 *Ahmed Hosam El-Din Baranek*

## Abstract

**Background:** The dialysis population represents the only group of patients to receive heparin three times per week, with a potential long-term cumulative effect associated with an increased risk of osteoporosis, aldosterone suppression and hyperkalemia, and a deterioration of lipid profile and endothelial function. **Aim of the Work:** to evaluate the adequacy of heparin therapy used for anticoagulation in pediatric patients receiving regular hemodialysis sessions, at pediatric dialysis unit, children`s hospital, Ain Shams University hospitals, during period from January 2018 to December 2018. **Patients and Methods:** This interventional study **was conducted on 48** pediatric hemodialysis patients who were attending dialysis setting, Pediatric Dialysis Unit, Children's Hospital, Ain Shams University during a period of 12 months. **Results:** Eleven patients (23%) had clinically detected coagulation abnormalities, bleeding in 6 cases (12.5%), 3 of them had bleeding with high ACT reading predialysis, 1 of them showed defective platelet functions by platelet function analyzer PFA which was repeated following phase II was normal. Clotting was detected in 4 cases (8%) and both bleeding and clotting were detected in 1 case (2%). **Conclusion:** CDCA occurred in 23% of the studied patients, among these bleeding was more prevalent. ACT as a bedside rapid test of anticoagulation adequacy during HD sessions did not offer predictive benefit over clinical evaluation, which is still considered a more accurate method. Moreover, HDF is proved beneficial in decreasing CDCA over conventional HD.

---

**Key words:** anticoagulation, children, unfractionated heparin, regular hemodialysis

---

## Introduction

Anticoagulation in hemodialysis is targeted to prevent activation of coagulation cascade during the procedure (**Kalra and Roy, 2012**). Appropriate anticoagulation for hemodialysis (HD) requires a subtle balance between under- and over-heparinization to prevent extracorporeal circuit (ECC) clotting and bleeding, respectively (**Kessler et al., 2015**).

Maintaining full patency in ECC during HD sessions is a prerequisite for optimal HD quality (**Suranyi and Chow, 2010**). A complex disturbance of the coagulation system is commonly encountered in patients at the terminal stage of chronic kidney disease (CKD), leading to considerable morbidity and mortality (**Jalal et al., 2010**).

Heparin is the most commonly used anticoagulant as it is easy to administer, has a short half-life and low cost (**Kalra and Roy, 2012**).

Of interest, the dialysis population represents the only group of patients to receive heparin three times per week, with a potential long-term cumulative effect associated with an increased risk of osteoporosis, aldosterone suppression and hyperkalemia, and a deterioration of lipid profile and endothelial function (**Lavainne et al., 2014**).

Unfractionated heparin (UFH) is metabolized by hepatic and vascular endothelial heparinases, in a dose dependent manner. Half-life can be modified by nonspecific binding to the endothelium, leukocytes and plasma proteins (**Chan et al., 2004**). UFH is highly charged and therefore nonspecific binding to plastic tubing and dialyzer membrane surfaces can occur altering its pharmacokinetics (**Kalra and Roy 2012**).

Anticoagulant management in HD patients is not evidence-based, and can therefore be challenged. Individual tailoring of anticoagulant treatment at any time remains difficult in daily practice. Given that a routine bedside biological monitoring protocol is not currently available, dialysis units have developed their own standard strategies to avoid both bleeding and clotting by pragmatically and empirically adjusting doses according to extracorporeal circuit (ECC) visual inspection and monitoring compression time at needle puncture site at the end of HD sessions (**Kessler et al., 2015**).

The use of biological monitoring is not clearly defined in routine clinical practice. The ideal test would be a rapid bedside whole-blood test that is accurate enough for quantifying the level of anticoagulation, and identifying under- or over-heparinization during HD. Different coagulation tests can be used, but their availability and the delay with obtaining results may differ from one dialysis center to another (**Herrero- Calvo et al., 2012**).

## **Aim of the Work**

**O**bjective evaluation of the adequacy of heparin therapy used for anticoagulation in pediatric patients receiving regular hemodialysis sessions, at pediatric dialysis unit, children`s hospital, Ain Shams University hospitals, during period from January 2018 to December 2018.

## Chapter 1

# Hemostasis in ESRD and Hemodialysis

### INTRODUCTION

End-stage renal disease (ESRD) is associated with profound effects on hemostasis ranging from thrombosis to bleeding complications. The pathogenesis of uremic bleeding is multifactorial. It has been attributed to platelet dysfunction, particularly platelet-platelet and platelet-vessel wall interactions. Renal replacement therapy has helped reduce bleeding episodes, but the risk of morbidity and mortality due to hemorrhage remains (**Goluza et al., 2011**).

Abnormalities of blood coagulation and fibrinolysis predispose uremic patients to hypercoagulable state carrying the risk of cardiovascular disease and thrombotic complications such as thrombosis of the vascular access wall (**Li et al., 2016**).

Interestingly, the dialysis population represents the only group of patients to receive heparin three times per week, with a potential long term cumulative effect associated with an increased risk of osteoporosis, aldosterone suppression and hyperkalemia, and a deterioration of lipid profile and endothelial function (**Lavainne et al., 2014**).
